MULTILINGUAL HIERARCHICAL ATTENTION NETWORKS FOR DOCUMENT CLASSIFICATION

Nikolaos Pappas        Andrei Popescu-Belis

JULY 2017
Abstract

Hierarchical attention networks have recently achieved remarkable performance for document classification in a given language. However, when multilingual document collections are considered, training such models separately for each language entails linear parameter growth and lack of cross-language transfer. Learning a single multilingual model with fewer parameters is therefore a challenging but potentially beneficial objective. To this end, we propose multilingual hierarchical attention networks for learning document structures, with shared encoders and/or attention mechanisms across languages, using multi-task learning and an aligned semantic space as input. We evaluate the proposed models on multilingual document classification with disjoint label sets, on a large dataset which we provide, with 600k news documents in 8 languages, and 5k labels. The multilingual models outperform strong monolingual ones in low-resource as well as full-resource settings, and use fewer parameters, thus confirming their computational efficiency and the utility of cross-language transfer.

1 Introduction

Learning word sequence representations has become increasingly useful for a variety of NLP tasks such as document classification (Tang et al., 2015; Yang et al., 2016), neural machine translation (NMT) (Cho et al., 2014; Luong et al., 2015), question answering (Chen et al., 2015; Kumar et al., 2015) and summarization (Rush et al., 2015). However, when data are available in multiple languages, representation learning must address two main challenges. Firstly, the computational cost of training separate models for each language grows linearly with their number, or even quadratically in the case of multi-way multilingual NMT as investigated by (Firat et al., 2016a) and (Johnson et al., 2016). Secondly, the models should be capable of cross-language transfer, which is an important component in human language learning (Ringbom, 2007).

Previous studies in document classification attempted to overcome these issues by employing multilingual word embeddings which allow direct comparisons and groupings across languages (Klementiev et al., 2012; Hermann and Blunsom, 2014; Ferreira et al., 2016). However, they are only applicable when common label sets are available across languages which is often not the case (e.g. Wikipedia or news). Moreover, despite recent advances in monolingual document modeling (Tang et al., 2015; Yang et al., 2016), multilingual models are still based on shallow networks.

In this paper, we propose Multilingual Hierarchical Attention Networks to learn shared document structures across languages for document classification with disjoint label sets, as opposed to training hierarchical attention networks (HANs).
in a language-specific manner (Yang et al., 2016). Our networks have a hierarchical structure with word and sentence encoders, along with attention mechanisms. Each of these can either be shared across languages or kept language-specific. To enable cross-language transfer, the networks are trained with multi-task learning across languages using an aligned semantic space as input. Fig. 1 displays document vectors, projected with t-SNE (van der Maaten, 2009), for two topics and two languages, either learned by monolingual HANs (a) or by our multilingual HAN (b). The multilingual HAN achieves better separation between ‘Europe’ and ‘Culture’ topics in English as a result of the knowledge transfer from Arabic.

We evaluate our model against strong monolingual baselines, in low-resource and full-resource scenarios, on a large multilingual document collection with 600k documents, labeled with general (1.2k) and specific topics (4.4k), from Deutsche Welle – which we will make available. Our multilingual models outperform monolingual ones in both scenarios, thus confirming the utility of cross-language transfer and the computational efficiency of the proposed architecture.

2 Related Work

Research on learning multilingual word representations is based on early work on word embeddings (Turian et al., 2010; Mikolov et al., 2013; Pennington et al., 2014). The goal is to learn an aligned word embedding space for multiple languages by leveraging bilingual dictionaries (Faruqui and Dyer, 2014; Ammar et al., 2016), parallel sentences (Gouws et al., 2015) or comparable documents such as Wikipedia pages (Yih et al., 2011; Al-Rfou et al., 2013). Bilingual embeddings were learned from word alignments using neural language models (Klementiev et al., 2012; Zou et al., 2013), including auto-encoders (Chandar et al., 2014). Despite progress at the word level, the document level remains comparatively less explored: the approaches proposed by Hermann and Blunsom (2014) or Ferreira et al. (2016) are based on shallow modeling and are applicable only to classification tasks with label sets shared across languages. These sets are costly to produce, and are often unavailable; here, we remove this constraint. We also develop deeper multilingual document models with hierarchical structure based on prior art at the word level.

Early work on neural document classification was based on shallow feed-forward networks, which required unsupervised pre-training (Le and Mikolov, 2014). Later studies focused on neural networks with hierarchical structure. Kim (2014) proposed a convolutional neural network (CNN) for sentence classification. Johnson and Zhang (2015) proposed a CNN for high-dimensional data classification, while Zhang et al. (2015) adopted a character-level CNN for text classification. Lai et al. (2015) proposed a recurrent CNN to capture sequential information, which outperformed simpler CNNs. Lin et al. (2015) and Tang et al. (2015) proposed hierarchical recurrent NNs and showed that they were superior to CNN-based models. Recently, Yang et al. (2016) demonstrated that a hierarchical attention network with bi-directional gated encoders outperforms traditional and neural baselines. Using such networks in multilingual settings has two drawbacks: the computational complexity increases linearly with the number of languages, and knowledge is acquired separately for each language. We address these issues by proposing a new multilingual model based on HANs, which learns shared document structures and to transfer knowledge across languages.

Early examples of attention mechanisms appeared in computer vision (Larochelle and Hinton, 2010; Denil et al., 2012). In text classification, studies which aimed to learn the importance of sentences included Yessenalina et al. (2010); Pappas and Popescu-Belis (2014); Yang et al. (2016) and more recently (Pappas and Popescu-Belis, 2017; Ji and Smith, 2017). In NMT, Bahdanau et al. (2015) proposed an attention-based encoder-decoder network, while Luong et al. (2015) proposed a local and ensemble attention model for NMT. Firat et al. (2016a) proposed a single encoder-decoder model with shared attention across language pairs for multi-way, multilingual NMT. Hermann et al. (2015) developed attention-based document readers for question answering. Chen et al. (2015) proposed a recurrent attention model over an external memory. Similarly, Kumar et al. (2015) introduced a dynamic memory network for question answering and other tasks. We propose hierarchical models with shared multi-level attention across languages, which, to our knowledge, has not been attempted before.
3 Background: Hierarchical Attention Networks for Document Classification

We adopt a general hierarchical attention architecture for document representation derived from a specific one proposed by Yang et al. (2016), displayed in Figure 2. We consider a dataset $D = \{(x_i, y_i), i = 1, \ldots, N\}$ made of $N$ documents $x_i$ with labels $y_i \in \{0, 1\}^k$. Each document $x_i = \{w_{i1}, w_{i2}, \ldots, w_{iKT}\}$ is represented by the sequence of $d$-dimensional embeddings of their words grouped into sentences, $T$ being the maximum number of words in a sentence, and $K$ the maximum number of sentences in a document.

The network takes as input a document $x_i$ and outputs a document vector $u_i$. In particular, it has two levels of abstraction, word vs. sentence. The former is made of an encoder $g_w$ with parameters $H_w$ and an attention $a_w$ with parameters $A_w$, while the latter similarly includes an encoder and an attention ($g_s$, $H_s$ and $a_s$, $A_s$). The output $u_i$ is used by the classification layer to determine $y_i$.

3.1 Encoder Layers

At the word level, the function $g_w$ encodes the sequence of input words $\{w_{it} \mid t = 1, \ldots, T\}$ for each sentence $i$ of the document, noted as:

$$h_w^{(it)} = g_w(w_{it}), t \in [1, T],$$  

and at the sentence level, after combining the intermediate word vectors $\{h_w^{(it)} \mid t = 1, \ldots, K\}$ to a sentence vector $s_i$ (see Section 3.2), the function $g_s$ encodes the sequence of sentence vectors $\{s_i \mid i = 1, \ldots, S\}$, noted as $h_s^{(i)}$.

The $g_w$ and $g_s$ functions can be any feedforward or recurrent networks with parameters $H_w$ and $H_s$ respectively. We consider the following networks: a fully-connected one, noted as Dense, a Gated Recurrent Unit network (Cho et al., 2014) noted as GRU\(^1\), and a bi-directional GRU which captures temporal information forward or backward in time, noted as biGRU. The latter is defined as a concatenation of the hidden states for each input vector obtained from the forward GRU, $g_w^f$, and the backward GRU, $g_w^b$:

$$h_w^{(it)} = [g_w^f(h_w^{(it)}); g_w^b(h_w^{(it)})]$$  

The same concatenation is applied for the hidden-state representation of a sentence $h_s^{(i)}$.

3.2 Attention Layers

A typical way to obtain a representation for a given word sequence at each level is by taking the last hidden-state vector that is output by the encoder. However, it is hard to encode all the relevant input information needed in a fixed-length vector. This problem is addressed by introducing an attention mechanism at each level (noted $a_w$ and $a_s$) that estimates the importance of each hidden state vector to the representation of the sentence or document meaning respectively. The sentence vector $s_i \in R^{d_w}$, where $d_w$ is the dimension of the word encoder, is thus obtained as follows:

$$\frac{1}{T} \sum_{t=1}^T \sum_{i=1}^N \alpha^{(it)}_w h_w^{(it)} = \frac{1}{T} \sum_{t=1}^T \sum_{j=1}^K \sum_{i=1}^N \exp(v_t^i u_w) h_w^{(it)}$$  

where $v_t^i = f_w(h_w^{(it)})$ is a fully-connected neural network with $W_w$ parameters. Similarly, the document vector $u \in R^{d_s}$, where $d_s$ is the dimension of the sentence encoder, is obtained as follows:

$$\frac{1}{K} \sum_{i=1}^K \sum_{j=1}^N \alpha^{(i)}_s h_s^{(i)} = \frac{1}{K} \sum_{i=1}^K \sum_{j=1}^N \sum_{a=1}^A \exp(v_j^a u_s) h_s^{(i)}$$  

The output of such a network is typically fed to a softmax layer for classification, with a loss based on the cross-entropy between gold and predicted labels (Tang et al., 2015) or a loss based on the negative log-likelihood of the correct labels (Yang et al., 2016). However, softmax overemphasizes the probability of the most likely label, which may

---

\(^1\)GRU is a simplified version of Long-Short Term Memory, LSTM (Hochreiter and Schmidhuber, 1997).
not be ideal for multi-label classification because each document will have very few labels with likely values (e.g. 0.2–0.9). Instead, it is more appropriate to have independent predictions for each label; as we also verified empirically in our preliminary experiments. Hence, we replace the softmax with a sigmoid function, for each document $i$ represented by the vector $u_i$, we model the probability of the $k$ labels as follows:

$$\hat{y}_i = p(y|u_i) = \frac{1}{1 + e^{-(W_c u_i + b_c)}} \in [0, 1]^k$$ (5)

where $W_c$ is a $d_s \times k$ matrix and $b_c$ is the bias term for the classification layer. The training loss based on cross-entropy is computed as follows:

$$\mathcal{L}(\theta) = -\frac{1}{N} \sum_{i=1}^{N} \mathcal{H}(y_i, \hat{y}_i)$$ (6)

where $\theta$ is a notation for all the parameters of the model (i.e. $H_w, A_w, H_s, A_s, W_c$), and $\mathcal{H}$ is the binary cross-entropy of the gold labels $y_i$ and predicted labels $\hat{y}_i$ for a document $i$. The above objective is differentiable and can be minimized with stochastic gradient descent (Bottou, 1998) or variants such as Adam (Kingma and Ba, 2014), to maximize classification performance.

4 Multilingual Hierarchical Attention Networks: MHANs

When multilingual data is available, the above network can be trained on each language separately but the needed parameters grow linearly with the number of languages. Moreover, they do not exploit common knowledge across languages or to transfer it from one to another. We propose here a hierarchical attention network with shared components across languages which have slower parameter growth compared to monolingual ones (hence sublinear), which enables knowledge transfer across languages. We now consider $M$ languages noted $L = \{L_l | l = 1, \ldots, M\}$, and a multilingual set of topic-labeled documents $D = \{(x_l^{(i)}, y_l^{(i)}) | i = 1, \ldots, N_l\}$ defined as above.

4.1 Sharing Components across Languages

To enable multilingual learning, we propose three distinct ways for sharing components between networks in a multi-task learning setting, depicted in Figure 3, namely: (a) sharing the parameters of word and sentence encoders, hence $\theta_{\text{enc}} = \{H_w, W_w^{(l)}, H_s, W_s^{(l)}, W_c^{(l)}\}$; (b) sharing the parameters of word and sentence attention models, hence $\theta_{\text{att}} = \{H_w^{(l)}, W_w^{(l)}, H_s^{(l)}, W_s^{(l)}, W_c^{(l)}\}$; and (c) sharing both previous sets of parameters, hence $\theta_{\text{both}} = \{H_w^{(l)}, W_w^{(l)}, H_s^{(l)}, W_s^{(l)}, W_c^{(l)}\}$. If $\theta_{\text{mono}} = \{H_w^{(l)}, W_w^{(l)}, H_s^{(l)}, W_s^{(l)}, W_c^{(l)}\}$ are the parameters of multiple independent monolingual models with Dense encoders, then we have:

$$|\theta_{\text{mono}}| > |\theta_{\text{enc}}| > |\theta_{\text{att}}| > |\theta_{\text{both}}|$$ (7)

where $|\cdot|$ is the number of parameters in a set. For GRU and biGRU encoders, the inequalities still hold, but swapping $|\theta_{\text{enc}}|$ and $|\theta_{\text{att}}|$. Excluding the classification layer which is necessarily language-specific\(^\text{2}\), the (a) and (b) networks have sublinear numbers of parameters and the (c) network has a constant number of parameters with respect to the number of languages.

Depending on the label sets, several types of document classification problems can be solved with such architectures. First, label sets can be common or disjoint across languages. Second, considering labels as $k$-hot vectors, $k = 1$ corresponds to a multi-class task, while $k > 1$ is a multi-label task. We focus here on the multi-label problem with disjoint label sets. Moreover, we assume an aligned input space i.e with multilingual word embeddings that have aligned meanings across languages (Ammar et al., 2016). With non-aligned word embeddings, the multilingual transfer is harder due to the complete lack of parallel information, as we show in Section 6.

4.2 Training over Disjoint Label Sets

For training, we replace the monolingual training objective (Eq. 6) with a joint multilingual

\(^2\)Note that the word embeddings are not considered as parameters in our setup because they are fixed during training.
objective that facilitates the sharing of components, i.e. a subset of parameters for each language \( \theta_1, \theta_2, ..., \theta_M \), across different language networks:

\[
\mathcal{L}(\theta_1, ..., \theta_M) = -\frac{1}{Z} \sum_{l} \sum_{i} N_{e} \mathcal{H}(y_i^{(l)}, \hat{y}_i^{(l)})
\]  

where \( Z = M \times N_{e} \) with \( N_{e} \) being the epoch size. Here it may also be beneficial to add a term \( \gamma_l \) for each language objective which encodes our prior knowledge about its importance; we keep this as future work. The joint objective \( \mathcal{L} \) can be minimized with respect to the parameters \( \theta_1, \theta_2, ..., \theta_M \) using SGD as before. However, when training on examples from different languages consecutively it is difficult to learn a shared space which works well across languages. This is because each language updates apply only on a subset of parameters and may bias the model away from other languages. To address this, we employ a training strategy similar to Firat et al. (2016a), who sampled parallel sentences for multi-way machine translation from different language pairs in a cyclic fashion. Here, we sample a document-label pair for each language at each iteration.

5 A New Corpus for Multilingual Document Classification: DW

Multilingual document classification datasets are usually limited in size, have target categories aligned across languages, and assign documents to only one category. However, classification is often necessary in cases where the categories are not strictly aligned and can be multiple per document. For instance, this is the case for online news agencies keeping track of multilingual news written and annotated by different journalists, a process which is expensive and time-consuming.

Two datasets for multilingual document classification have been used in previous studies: Reuters RCV1/RCV2 (6,000 documents, 2 languages and 4 labels) and TED talk transcripts (12,078 documents, 12 languages and 15 labels) introduced by Hermann and Blunsom (2014). The former is tailored for evaluating word embeddings aligned across languages, rather than complex multilingual document models. The latter is twice as large and covers more languages, in a multi-label setting, but biases evaluation by including translations of talks in all languages.

Here, we present and use a much larger dataset collected from Deutsche Welle, Germany’s public international broadcaster. The DW dataset contains nearly 600,000 documents annotated by journalists with several topic labels in 8 languages, shown in Table 1. Documents are on average 2.6 times longer than in Yang et al.’s (2016) monolingual dataset (436 vs. 163 words). There are two types of labels, namely general topics \((Y_g)\) and specific ones \((Y_s)\), described by one or more words. We consider (and count in Table 1) only those specific labels that appear at least 100 times, to avoid sparsity issues.

The number of labels varies greatly across DW’s language services. Moreover, we found for instance that only 25-30% of the labels could be manually aligned between English and German. The commonalities are mainly concentrated on the most frequent labels, reflecting a shared top-level division of the news domain, but the long tail exhibits significant independence across languages.

6 Evaluation

We evaluate our multilingual models on full-resource and low-resource scenarios of multilingual document classification over disjoint label sets on the Deutsche Welle corpus.

6.1 Settings

The corpus is split per language into 80% for training, 10% for validation and 10% for testing. We evaluate both type of labels \((Y_g, Y_s)\) on a full-resource scenario and only the general topics \((Y_g)\) on a low-resource scenario. We report the micro-averaged F1 scores for each test set, as in previous work (Hermann and Blunsom, 2014).

Model configuration. For all models, we use the aligned pre-trained 40-dimensional multilingual embeddings trained on the Leipzig corpus us-

| Languages | Documents | \( \bar{s} \) | \( \bar{w} \) | \( |Y_g| \) | \( |Y_s| \) |
|-----------|-----------|-------------|-------------|----------|----------|
| English   | 112,816   | 17.9        | 516.2       | 527      | 1,058    |
| German    | 132,709   | 22.3        | 424.1       | 367      | 809      |
| Spanish   | 75,827    | 13.8        | 412.9       | 159      | 684      |
| Portuguese| 39,474    | 20.2        | 571.9       | 95       | 301      |
| Ukrainian | 35,423    | 17.6        | 342.9       | 28       | 260      |
| Russian   | 108,076   | 16.4        | 330.1       | 102      | 814      |
| Arabic    | 57,697    | 13.3        | 357.7       | 91       | 344      |
| Persian   | 36,282    | 18.7        | 538.4       | 71       | 127      |

Table 1: Statistics of the Deutsche Welle corpus: \( \bar{s} \) and \( \bar{w} \) are the average numbers of sentences and words per document.
ing multi-CCA from Ammar et al. (2016). The non-aligned embeddings are trained with the same method and data. We zero-pad documents up to a maximum of 30 words per sentence and 30 sentences per document. The hyper-parameters were selected on the validation sets. We made the following settings: 100-dimensional encoder and attention embeddings (at every level), relu activation function for all intermediate layers, batch size of 16, epoch size of 25k, and optimization using SGD with Adam until convergence.

All the hierarchical models have Dense encoders in both scenarios (Tables 2, 4, and 5), and GRU and biGRU in the full-resource scenario for English+Arabic (Table 3). For the low-resource scenario, we define three levels of data availability: tiny from 0.1% to 0.5%, small from 1% to 5% and medium from 10% to 50% of the original training set. We report the average $F_1$ scores on the test set for each level based on discrete increments of 0.1, 1 and 10 respectively. The decision threshold for the full-resource scenario is set to 0.4 for $|Y_s| < 400$ and 0.2 for $|Y_s| \geq 400$, and for the low-resource scenario it is 0.3 for all sets.

**Baselines.** We compare against the following monolingual neural networks, with shallow or hierarchical structure. These networks are based on the state of the art in the field, reviewed in Section 2, and thus represent strong baselines.

- **NN:** A neural network which feeds the average vector of the input words directly to a classification layer, as the common baseline for multilingual document classification by Klementiev et al. (2012).
- **HNN:** A hierarchical network with encoders and average pooling at every level, followed by a classification layer.

- **HAN:** A hierarchical network with encoders and attention, followed by a classification layer. This model is the one proposed by Yang et al. (2016) adapted to our task.

When training our multilingual system with the three options described in Section 4.1 noted as Enc, Att and Both, we use in fact the multilingual version of the third monolingual baseline, as illustrated in Fig. 3, trained with the objective of Eq. 8.

### 6.2 Results

#### Full-resource Scenario

Table 2 displays the results of full-resource document classification for general and specific labels. In particular, on the left, the performance on the English sub-corpus is shown when English and an auxiliary sub-corpus are used for training, and on the right the performance on the auxiliary sub-corpus is shown when that sub-corpus and English are used for training.

The multilingual model trained on pairs of languages outperforms on average all the examined monolingual models, from simple bag-of-words neural models to hierarchical neural models using average pooling or attention. The best-performing multilingual architecture is the one with shared attention across languages, especially when tested...
on English (documents and labels). Interestingly, this reveals that the transfer of knowledge across languages in a full-resource setting is maximized with language-specific word and sentence encoders, but language-independent (i.e. shared) attention for both words and sentences.

However, when transferring from English to Portuguese (en→pt), Russian (en→ru) and Persian (en→fa) on general categories, it is more effective to have only language-independent components. We hypothesize that this is due to the underlying commonness between the label sets rather than the relationship between languages. The consistent gain for English as target could be attributed to the alignment of the word embeddings to English and to the large number of English labels, which makes it easier to find multilingual labels from which to transfer knowledge.

We quantify now the impact of three important model choices on the performance: encoder type, word embeddings, and number of languages used for training. In Table 3, we observe that when we replace the Dense encoder layers with GRU or biGRU layers, the improvement from the multilingual training is still present. In particular, the multilingual models with shared attention are superior to alternatives regardless of the employed encoders. For reference, using simply logistic regression with bag-of-words (counts) for classification leads to $F_1$ scores of 75.8% in English and 81.9% in Arabic, using many more parameters than biGRU: 56.5M vs. 410k in English and 5.8M vs. 364k in Arabic.

In Table 4, we observe that when we train our multilingual model (MHAN-att) on eight languages at the same time, the $F_1$ scores improve across languages – for both types of labels, general or specific – while the number of parameters per language decreases, by 36% for $Y_{general}$ and 20% for $Y_{specific}$. Lastly, when we train the same model with word embeddings that are not aligned across languages, the performance of the multilingual model drops significantly. An input space that is aligned across languages is thus crucial.

**Low-resource Scenario.** We assess the ability of the multilingual attention networks to transfer knowledge across languages in a low-resource scenario. The results for seven languages when trained jointly with English are displayed in Table 5. In all cases, at least one of the multilingual models outperforms the monolingual one, which demonstrates the usefulness of multilingual training for low-resource document classification.

Moreover, the improvements obtained from our multilingual models for lower levels of availability (tiny and small) are larger than in higher levels.
Figure 5: Cumulative true positive (TP) difference between monolingual and multilingual (ensemble) models for topic classification with specific labels, in the full resource scenario.

(medium). This is also clearly observed in Figure 4 with our multilingual attention network ensemble, i.e. when we do model selection among the three multilingual variants on the development set. The best performing architecture in a majority of cases is the one which shares both the encoders and the attention mechanisms across languages. Moreover, this architecture also has the fewest number of parameters for the document modeling.

This promising finding for the low-resource scenario means that the classification performance can greatly benefit from the multilingual training (sharing encoders and attention) without increasing the parameters beyond that of a single monolingual document model. Nevertheless, in a few cases, we observe that the other two architectures, with increased complexity perform better than the “shared both” model. For instance, sharing encoders is superior to alternatives for Arabic language, i.e. the knowledge transfer benefits from shared word and sentence representations. Hence, to generalize to a large number of languages, we may need to consider more sophisticated models than sharing a monolingual document model across languages. Lastly, we did not generally observe a negative (or positive) correlation of the closeness between languages with the performance in the low-resource scenario, although the largest improvements were observed on languages more related to English (German, Spanish, Portuguese) than others (Arabic).

6.3 Qualitative Analysis

We analyze the performance of the model over the full range of labels, to observe on which type of labels it performs better than the monolingual model, and provide some qualitative examples. Figure 5 shows the cumulative true positive (TP) difference between the monolingual and multilingual models on the Arabic and German, Portuguese and Russian test sets, ordered by label frequency. We can observe that the cumulative TP difference of multilingual model consistently keeps increasing as the frequency of the label decreases. This shows that labels across the entire range of frequencies benefit from joint training with English and not only a subset, e.g. only frequent labels.

For example, the top 5 labels on which the multilingual model performed better than the monolingual one for en → de were: russland (21), berlin (19), irak (14), wahlen (13) and nato (13), while for the opposite direction those were: germany (259), german (97), soccer (73), football (47) and merkel (25). These topics are likely better covered in the respective auxiliary language which helps the multilingual model to better distinguish them in the target language. This is also observed in Figure 1, as the improved separation of topics using multilingual model vs. monolingual ones.

7 Conclusion

We proposed multilingual hierarchical attention networks for document classification and showed that they can benefit both full-resource and low-resource scenarios by using fewer parameters than with monolingual networks. In the former scenario, the most beneficial was to share only the attention mechanisms, while in the latter one, to share the encoders along with the attention mechanisms. These results confirm the merits of language transfer, which is also an important component of human language learning (Odlin, 1989; Ringbom, 2007). Moreover, our study broadens the applicability of multilingual document classification, since our framework is not restricted to common label sets.

There are several future directions for this study.
In their current form, our models cannot generalize to languages without any example, as attempted by Firat et al. (2016b) for neural MT. This could be achieved by a label-size independent classification layer as in zero-shot classification (Qiao et al., 2016; Nam et al., 2016). Moreover, although we explored three distinct architectures, other configurations could be examined to improve document modeling, for example by sharing the attention mechanism at the sentence-level only. Lastly, the learning objective could be further constrained with sentence-level parallel information, to embed multilingual vectors of similar topics more closely together in the learned space.
